\textit{Klebsiella pneumoniae} is emerging as an important nosocomial pathogen due to its rapidly increasing multidrug resistance, which has led to a renewed interest in polymyxin antibiotics, such as colistin, as antibiotics of last resort. However, heteroresistance (i.e., the presence of a subpopulation of resistant bacteria in an otherwise susceptible culture) may hamper the effectiveness of colistin treatment in patients. In a previous study, we showed that colistin resistance among extended-spectrum-beta-lactamase (ESBL)-producing \textit{K. pneumoniae} isolates emerged after the introduction of selective digestive tract decontamination (SDD) in an intensive care unit (ICU). In this study, we investigated heteroresistance to colistin among ESBL-producing \textit{K. pneumoniae} isolates by using population analysis profiles (PAPs). We used whole-genome sequencing (WGS) to find five heteroresistant subpopulations, with colistin MICs ranging from 8 to 64 mg/liter, which were derived from five clonally related, colistin-susceptible clinical isolates. WGS revealed the presence of mutations in the \textit{lpxM}, \textit{mgrB}, \textit{phoQ}, and \textit{yciM} genes in colistin-resistant \textit{K. pneumoniae} isolates. In two strains, \textit{mgrB} was inactivated by an IS3-like or IS\textit{Kpn}14 insertion sequence element. Complementation in \textit{trans} with the wild-type \textit{mgrB} gene resulted in these strains reverting to colistin susceptibility. The MICs for colistin-susceptible strains increased 2- to 4-fold in the presence of the mutated \textit{phoQ}, \textit{lpxM}, and \textit{yciM} alleles. In conclusion, the present study indicates that heteroresistant \textit{K. pneumoniae} subpopulations may be selected for upon exposure to colistin. Mutations in \textit{mgrB} and \textit{phoQ} have previously been associated with colistin resistance, but we provide experimental evidence for roles of mutations in the \textit{yciM} and \textit{lpxM} genes in the emergence of colistin resistance in \textit{K. pneumoniae}.

\textit{Klebsiella pneumoniae} is emerging as an important nosocomial pathogen due to rapidly increasing resistance to practically all currently available antibiotics, in particular carbapenems (1, 2). This Gram-negative opportunistic pathogen can cause wound and urinary tract infections and other life-threatening, hospital-acquired infections, such as pneumonia, bacteremia, and postoperative meningitis (3, 4). Due to increasing multidrug resistance (MDR) among Gram-negative bacteria, including \textit{K. pneumoniae}, and the lack of novel antibiotics to treat infections caused by MDR Gram-negative bacteria (5), there is a renewed interest in the antibiotic colistin as a therapy of last resort (6).

Colistin (polymyxin E) is a cationic polypeptide with a lipid tail which targets anionic lipopolysaccharide (LPS) molecules in the outer membranes of Gram-negative bacteria, introducing changes in the permeability of the membrane which lead to leakage of cell contents and, finally, cell death (7, 8). Resistance to colistin among Gram-negative bacteria in clinical isolates was reported recently (9–11). Several strategies are employed by bacteria to gain resistance to colistin, including LPS modifications, particularly modifications of lipid A, the use of efflux pumps, and overexpression of outer membrane proteins (12). Resistance to colistin in clinical isolates may go undetected when traditional \textit{in vitro} antibiotic susceptibility testing is used, because of heteroresistance, which denotes the presence of subpopulations of bacterial cells with higher levels of antibiotic resistance than those of the rest of the population in the same culture (13). This phenomenon was described recently for Gram-negative organisms including \textit{Pseudomonas aeruginosa} (14), \textit{Acinetobacter baumannii} (15, 16), and \textit{Enterobacter cloacae} (17).

In a previous study (18), we showed that colistin resistance among extended-spectrum beta-lactamase (ESBL)-producing \textit{K. pneumoniae} isolates emerged after exposure to colistin as part of selective digestive tract decontamination (SDD) in an intensive care unit (ICU), and we postulated that this may be explained by the presence of heteroresistant subpopulations of the colistin-susceptible MDR strains.

In the present study, the existence of colistin-resistant subpopulations among ESBL-producing \textit{K. pneumoniae} isolates was investigated. Through whole-genome sequencing (WGS) and...
complementation of mutated alleles in \textit{trans}, the roles of mutations in resistance to colistin in \textit{K. pneumoniae} were determined.

**MATERIALS AND METHODS**

Clinical data and bacterial isolates. \textit{K. pneumoniae} isolates were collected during a study on the emergence of colistin resistance in \textit{Enterobacteriaceae} before and after the introduction of SDD in an ICU (18). Briefly, SDD, a topical mixture of antibiotics, including tobramycin, colistin, and amphotericin B at doses (given four to eight times daily) of 80, 100, and 500 mg, respectively, was introduced in 2002 to control an outbreak of ESBL-producing \textit{K. pneumoniae} in an ICU. Reexamination of stored isolates from surveillance and clinical cultures from ICU patients before and after the start of SDD revealed that all tested isolates obtained before the start of SDD were colistin susceptible, whereas 71\% of isolates from cultures obtained thereafter were resistant. Molecular typing of the isolates revealed that most of them were clonally related (18).

In this study, we included a total of 13 strains: eight genetically related ESBL-producing \textit{K. pneumoniae} clinical isolates (one isolate per patient) with known colistin MICs and five heteroresistant subpopulations of these isolates. Genetic relatedness was determined by use of the DiversiLab system (bioMérieux, Marcy l‘Étoile, France) according to the manufacturer’s instructions. The eight clinical isolates included six colistin-susceptible isolates, one of which was obtained before the start of SDD and five thereafter, and two colistin-resistant isolates obtained after the start of SDD. The six colistin-susceptible isolates and one of the two colistin-resistant isolates were genotypically identical based on DiversiLab typing.

\textit{K. pneumoniae} ATCC 700603 (ATCC, Manassas, VA) was included as a colistin-susceptible reference strain. The identities of all isolates were confirmed by matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF) analysis according to the manufacturer’s instructions, and strains were stored at -80°C before the investigations described in this study.

Antibiotic susceptibility testing. Routine antimicrobial susceptibility testing was performed by use of a Vitek 2 Advanced Expert system and Etest (bioMérieux, Marcy l‘Étoile, France), using the European Committee on Antimicrobial Susceptibility Testing (EUCAST) breakpoints (http://www.eucast.org/clinical_breakpoints). The presence of ESBLs was determined with the double-disk synergy test (19). The MICs of colistin against the \textit{K. pneumoniae} strains were determined by broth microdilution testing (http://www.eucast.org/guidance_documents) using cation-adjusted Mueller-Hinton broth (MHB). Determination of the colistin MICs of electrotransformed strains was performed with MHB supplemented with 10 mg/liter tetracycline.

PAPs. To investigate the presence of colistin heteroresistance, population analysis profiles (PAPs) were determined for two replicates by spiral plating 50-μl aliquots of the starting bacterial cell suspension (corresponding to a 0.5 McFarland standard for \textit{K. pneumoniae} cultures grown on blood agar plates for 24 h at 37°C, approximately 10⁸ CFU/ml) on Mueller-Hinton agar plates with or without colistin sulfate (0.5, 1, 2, 3, 4, 5, 6, 8, and 10 mg/liter; Sigma-Aldrich, Zwijndrecht, The Netherlands) as described by Li et al. (20). After 24 h of incubation at 37°C, the number of colonies was counted. Colistin heteroresistance was defined as the presence of a colistin-susceptible isolate with a colistin MIC of <2 mg/liter in which detectable colistin-resistant subpopulations were able to grow in the presence of ≥2 mg/liter colistin (20). The detection limit of colistin-resistant subpopulations was 20 CFU/ml.

**Genome sequencing and assembly.** Genomic DNAs of \textit{K. pneumoniae} isolates were isolated from overnight cultures grown in Luria broth at 37°C with shaking at 250 rpm by use of a Wizard Genomic DNA purification kit (Promega, Madison, WI) according to the manufacturer’s instructions. Sequence libraries were prepared with a Nextera XT kit (Illumina, San Diego, CA) used according to the manufacturer’s instructions. Libraries were sequenced on an Illumina MiSeq system with a 500-cycle (2 × 250 bp) MiSeq reagent kit v2. High-throughput sequence (HTS) data were analyzed for quality with FastQC (http://www.bioinformatics.babraham.ac.uk/projects/fastqc/), and raw 2- by 250-bp paired-end reads were filtered with Neson 0.109 (http://github.com/Victorian-Bioinformatics-Consortium/nesoni). \textit{De novo} genome assembly was performed with SPAdes 2.5.1 (21), with k-mers 25, 35, 45, 57, and 69, using the following cutoffs for the minimum contig/scaffold: a size of 500 bp and average nucleotide coverage (10-fold).

**Phylogenetic analysis.** Publicly available WGS sequence data for 25 \textit{K. pneumoniae} strains were downloaded from the NCBI databases in February 2016. The strains used in phylogenetic analysis were selected to cover all \textit{K. pneumoniae} clades, as previously determined by Holt et al. (22). For strains for which only raw sequence reads were available, assemblies were generated with SPAdes 2.5.1 (21), as described above. To ensure consistent gene prediction and annotation of all 38 genomes in this study, all genome sequences were reannotated with PROKKA v1.10, using the default settings (23). To identify the core genome of these strains, first an all-against-all protein BLAST sequence similarity search of annotated and translated gene sequences was performed with default settings, except for an E value of 1e-05. Based on the protein BLAST output, orthologous groups were determined and clustered using OrthoVogoule v1.03 (24) (settings -u and -o 50) and MCL v14-137 (25) (settings -i 1.5), respectively. The nucleotide sequences of orthologous groups containing exactly one representative protein from each of the \textit{K. pneumoniae} genomes were extracted and then aligned using MUSCLE v3.8.31 (26). Gaps were removed from each alignment by using trimAl v1.6 (27), resulting in alignments of equal length (core genome alignments) which were then concatenated. Subsequently, Parsnp v1.2 (28) (settings -r!, -c, and -C 1000) was used to construct a maximum likelihood phylogenetic tree from the variable positions in these core genome alignments. The tree was midpoint rooted and visualized using FigTree software (v1.4.2; http://tree.bio.ed.ac.uk/software/figtree).

**Identification of SNPs and indels.** Mapping of the Neson-filtered reads against the complete genome sequence of \textit{K. pneumoniae} MGH 78578 (NCBI accession number NC_009648) was performed with Bowtie2 v2.2.0 (29) (settings -X 1200, and -a). Genomic repeats were removed from the analyses by filtering out reads that mapped to multiple positions in the \textit{K. pneumoniae} MGH 78578 genome. To call single nucleotide polymorphisms (SNPs) and insertions and deletions (indels), SAMtools 0.18 (30) was used with the following settings: Q score of ≥50, mapping quality of ≥30, mapping depth of ≥10 reads, consensus of ≥75% to support a call, and ≥1 supporting reads in each direction.

**Multilocus sequence typing (MLST) and identification of antibiotic resistance genes.** Sequence types of the isolates were determined by submitting the genome assemblies to MLST, version 1.8 (31). Antibiotic resistance genes in the genome assemblies were identified by ResFinder v2.1 (32).

**Complementation in trans.** The genes that were mutated in the colistin-resistant \textit{K. pneumoniae} strains were amplified from both the susceptible and resistant strains by PCR using 2× Phusion HF master mix (Thermo Scientific, Landsmeer, The Netherlands) and the primers listed in Table S1 in the supplemental material. The amplified fragments were cloned into the PCR-Trap cloning system (GenHunter, Nashville, TN), and the resulting plasmids (encoding resistance to tetracycline) were transformed into electrocompetent colistin-susceptible or -resistant \textit{K. pneumoniae} strains by electroporation. The cloned amplicons were sequenced to ensure the absence of errors introduced during PCR (Macrogen Europe, Amsterdam, The Netherlands). Transformants were selected by overnight incubation at 37°C on Luria agar supplemented with 10 mg/liter of tetracycline. The \textit{lacZ} gene fragment encoding the \textit{LacZ} α-peptide was used as a control insert.

**Accession number(s).** Sequence data from this study were deposited in NCBI’s Short Read Archive (SRA) under accession number SRA354747.

* Isolate identifiers consist of unique numbers used in Fig. 1 and 2; letters indicate the code for the patient and whether the strain was susceptible (S) or resistant (R) to colistin. The isolate from patient A was obtained before the introduction of SDD in the ICU, and the remaining seven were obtained thereafter. Clonality was determined by phylogenetic analysis. MICs were determined by the broth microdilution method. The different SNPs, a deletion, and the inactivation of genes due to IS element insertions are indicated in the mutation columns. Heteroresistant strains are indicated with shading. ST, sequence type; ND, not determined.

RESULTS

Antimicrobial susceptibility and colistin heteroresistance. An overview of the 13 *K. pneumoniae* strains included in this study is listed in Table 1; these strains included eight clinical isolates and five heteroresistant subpopulations. After retesting of antibiotic susceptibilities and confirmation of the presence of the ESBL phenotype by the double-disk synergy test, seven of the eight initially ESBL-producing *K. pneumoniae* clinical isolates were again found to be ESBL positive (isolate 3-CR lost the ESBL phenotype). None of the strains was resistant to carbapenem antibiotics. The six colistin-susceptible isolates had colistin MICs ranging from 1 to 2 mg/liter, and the two colistin-resistant strains had colistin MICs of 16 and 64 mg/liter.

PAPs revealed the presence of heteroresistance in five clinical isolates (Table 1) (isolates 4-DS, 6-ES, 8-FS, 10-GS, and 12-HS) initially considered colistin susceptible based on MICs ranging from 1 to 2 mg/liter. Subpopulations of these colistin-heteroresistant isolates grew in the presence of colistin at concentrations of 3 to 10 mg/liter (Fig. 1). The MICs for the resistant subpopulations 5-DR, 7-ER, 9-FR, 11-GR, and 13-HR were 32, 48, 16, 8, and 64 mg/liter, respectively (Table 1). The proportion of resistant colonies was on the order of 10⁻⁶. The colistin-susceptible reference strain ATCC 700603 survived in the presence of up to 0.5 g/liter colistin sulfate, and no heteroresistant subpopulations were observed.

Phylogenetic analysis of colistin-susceptible and colistin-resistant *K. pneumoniae* isolates. A phylogenetic tree (Fig. 2A) for *K. pneumoniae* was generated based on the core genome sequence of 25 publicly available *K. pneumoniae* sequences and the 13 sequenced genomes of the *K. pneumoniae* isolates (Table 1). The core genome consisted of 2,637 orthogroups, with a total alignment length of 2,013,123 bp and 209,626 polymorphic sites. The core genome-based phylogenetic tree recapitulated the previously observed population structure of *K. pneumoniae sensu lato*, which includes *Klebsiella quasipneumoniae* (clade KpII) and *Klebsiella variicola* (clade KpIII) (22, 33, 34). Seven of the eight clinical isolates from the nosocomial outbreak were closely related to each other and clustered in the *K. pneumoniae* (KpI) clade. A single colistin-resistant isolate (3-CR) was assigned to clade KpIII and therefore appeared to be unrelated to the other isolates from the outbreak. All other strains from the outbreak (seven clinical isolates and five heteroresistant subpopulations) had the same sequence type, i.e., ST-43. These data confirm the previously reported existence of an outbreak with closely related *K. pneumoniae* isolates in an ICU (18).

Although the isolates belonged to the same sequence type, a repertoire of distinctly different antibiotic resistance genes was observed (Fig. 2B). The isolates carried several antibiotic resistance genes, including aminoglycoside resistance genes and β-lactam resistance genes.

Mutations associated with colistin resistance. SNPs and indels were determined for all paired colistin-susceptible and colistin-resistant isolates. In addition, we determined whether full-length copies of the *mgrB* and *phoQ* genes were present in the
isolates, as mutations leading to deletion or inactivation of these genes are a common cause of colistin resistance in *K. pneumoniae* (12, 35–39).

A limited number (1 to 4) of SNPs (see Table S2 in the supplemental material) and indels (see Table S3) distinguished the outbreak isolates. In comparisons of paired colistin-susceptible and colistin-resistant strains originating from the same patients, we identified mutations in *mgrB* that led to disruption of the gene in three colistin-resistant isolates (2-BR, 5-DR, and 13-HR). The event that led to the inactivation of *mgrB* was different for each strain. In strain 2-BR, an IS element (IS3-like) was inserted into *mgrB*. In strain 5-DR, the element IS*Kpn14* disrupted *mgrB*. Strain 13-HR had a 4.2-kb deletion including the *mgrB* gene. In all other colistin-resistant strains, *mgrB* was not mutated, meaning that other mutations must have led to the colistin resistance phenotypes of 7-ER, 9-FR, and 11-GR.

Interestingly, in these isolates, nonsynonymous SNPs were identified in genes that had predicted roles in outer membrane biosynthesis. Since the outer membrane is the main target of colistin, mutations in genes involving outer membrane biosynthesis may contribute to colistin resistance. In the strains from patient E, the only SNP difference between the colistin-susceptible (6-ES) and colistin-resistant (7-ER) isolates was a nonsynonymous SNP causing a V43G amino acid substitution encoded within the *yciM* gene. A mutation in *phoQ*, resulting in an A21S amino acid change, was identified in the colistin-resistant isolate 9-FR. The colistin-susceptible and colistin-resistant strains from patient G (10-GS and 11-GR, respectively) differed from each other by only 2 SNPs. One of these SNPs mapped to the *lpxM* gene, causing a V30G substitution.

**Mutations in *mgrB*, *yciM*, *phoQ*, and *lpxM* contribute to colistin resistance.** To verify whether the IS element insertions and amino acid substitutions identified by WGS contributed to colistin resistance, the colistin-susceptible and -resistant strain

---

**FIG 2** Phylogenetic tree and antibiotic resistance genes of *K. pneumoniae* strains. (A) The phylogenetic tree represents a concatenated alignment of 2,637 core orthogroups, with a combined length of 2,013,123 bp and 209,626 polymorphic sites, of 38 *K. pneumoniae* strains. The strains sequenced as part of this study are highlighted in color (orange, colistin-susceptible isolates; and blue, colistin-resistant isolates). (B) Antibiotic resistances detected in the *K. pneumoniae* strains that were sequenced as part of this study. Classes of antibiotic resistance genes are indicated as follows: A, aminoglycoside resistance genes; B, β-lactam resistance genes; C, chloramphenicol resistance genes; Q, quinolone resistance genes; S, sulfonamide resistance genes; and T, trimethoprim resistance genes.
FIG 3 Experimental validation of the roles of identified mutations in colistin resistance. Wild-type and mutated mgrB, yciM, phoQ, and lpxM alleles were cloned into corresponding K. pneumoniae strains by use of a PCR-TRAP cloning system (red). The strains from which the corresponding genes originated are indicated in parentheses. A vector containing a gene encoding the LacZ α-peptide of E. coli was used as a vector control (blue). The colistin MICs for the electrotransformed K. pneumoniae strains were determined by reference broth microdilution testing using cation-adjusted Mueller-Hinton broth supplemented with 10 mg/liter tetracycline. The colistin MIC resistance breakpoint (i.e., 2 mg/liter) is indicated with a black dashed line. Significant differences (P < 0.05; Mann-Whitney test) are indicated by double asterisks. The y axis was plotted on a log2 scale.

pairs were complemented in trans with the wild-type and mutated genes. Transformation of the strains with a control plasmid containing the lacZ gene did not alter the MIC of colistin for any strain. Complementation in trans with plasmids harboring the parental mgrB gene resulted in a reversal toward colistin susceptibility in isolates 2-BR and 5-DR (Fig. 3). Transformation in trans for the 12-HS and 13-HR pair was not performed due to difficulties in cloning the 4.2-kb deleted region spanning mgrB. Complementation with the mutated forms of phoQ, yciM, and lpxM resulted in decreased susceptibility to colistin. Electrotransformation of the colistin-susceptible strain 6-ES with a plasmid containing the mutated yciM gene resulted in a 3-fold increase in the MIC of colistin. The phoQ and lpxM mutations resulted in a 4-fold increased MIC of colistin for strain 8-FS and a 2-fold increased MIC of colistin for strain 10-GS, respectively. These observations indicate that mutations in yciM, phoQ, and lpxM are dominant when present in trans with the corresponding wild-type alleles, resulting in a colistin resistance phenotype. Because the deletions and inactivations of mgrB are loss-of-function mutations, they are recessive in the presence of the intact mgrB gene.

**DISCUSSION**

In a previous study, we showed that prolonged use of colistin as part of SDD in an outbreak setting resulted in the emergence of colistin resistance among ESBL-producing K. pneumoniae clinical isolates (18). The main finding of the present follow-up study is that heteroresistance among these apparently susceptible isolates forms a reservoir for the emergence of colistin resistance during treatment.

Heteroresistance has been recognized in both Gram-positive and Gram-negative bacteria and is a phenomenon where subpopulations of seemingly isogenic bacteria exhibit a range of susceptibilities to a particular antibiotic (13). Heteroresistance can be intrinsic or acquired. Intrinsic heteroresistance occurs without preexposure to the antibiotic, but heteroresistance may also be acquired or induced after initial exposure to antibiotics (13). Heteroresistance may have an impact on the outcome of clinical infection, particularly because its detection may be difficult by routine microbiology susceptibility testing (40). The PAP method used in the present study is considered the gold standard for determining heteroresistance (13). Phylogenetic analysis confirmed the clonality of all clinical isolates (excluding 3-CR). However, the absence of overlapping SNPs between clonal colistin-resistant isolates, isolated from different patients over a time span of 4 years, argues in favor of acquired, de novo resistance in individual strains under SDD use, rather than selection of preexisting mutants or transmission of the resistant strains between patients.

Although heteroresistance has previously been described for K. pneumoniae (41, 42), data on the molecular basis of colistin resistance in this species are scarce. Studies have recently shown that mutations in the genes encoding the PhoPQ two-component system and inactivation of the mgrB gene are important pathways by which K. pneumoniae can acquire resistance to colistin (43). In the present study, mutations in phoPQ and mgrB were found in four of the six analyzed isolates.

Mutations in the phoQ gene are a common mechanism by which Gram-negative bacteria, including K. pneumoniae, gain resistance to colistin (12, 38, 39). PhoQ is a sensor histidine kinase which, together with its cognate response regulator, PhoP, forms a two-component system (2CS). PhoPQ is activated under a variety of conditions, including low pH, low concentrations of Mg2+, and the presence of antimicrobial peptides, including colistin. Activation of PhoPQ leads to the expression of genes that modify LPS in a variety of ways, including deacylation of lipid A or modification of lipid A by 4-amino-4-deoxy-L-arabinose, leading to colistin resistance (12). We found that a mutation in phoQ resulting in an amino acid change (A21S) in the sensor domain of PhoQ which...
leads to colistin resistance was dominant over the nonmutated copy of phoQ. A mutation in Salmonella phoQ, resulting in a threonine-to-isoleucine change at position 48, in the sensor domain of the PhoQ protein, was also found to be dominant, as it constitutively increased phosphorylation of the response regulator PhoP (44, 45). A similar mechanism may explain why the phoQ mutation of Klebsiella pneumoniae strain 9-FR is dominant. Several studies have recently shown that inactivation of the mgrB gene, which encodes a negative regulator of the 2CS PhoPQ, contributes to cell wall integrity by regulating LPS acylation of lipid A, thereby making the strain more resistant to colistin. To our knowledge, this is the first time that mutations in K. pneumoniae lead to colistin resistance was dominant over the nonmutated allele. Our study highlights the multiple evolutionary trajectories that can lead to colistin resistance in K. pneumoniae and underscores the importance of monitoring the existence of colistin-resistant subpopulations in diagnostic susceptibility testing due to cross-resistance to the host anti-microbial lysozyme.
